Abstract
It was more than 25 years ago that two German researchers quietly associated supplementation of glucosamine to horses with improvement of joint disease. In the 25 years since, glucosamine and its related chemical chondroitin have become the most extensively used non-allopathic treatment for articular inflammation and arthritis in horses. While the practice of supplementing arthritic horses with these products has, in earlier times, been considered a complete unknown in terms of safety and efficacy, the story is quite different today. An expanding body of knowledge on glucosamine continues to raise scientific curiosity about the general principles and cellular basis of treating equine osteoarthritis and inflammation with glucosamine-based nutraceuticals. This review critically interprets the published in vivo studies designed to investigate glucosamine-based nutraceuticals for horses with joint pain and/or inflammation. These studies have contributed valuable preliminary information as to the possible usefulness of glucosamine-based nutraceuticals in horses, and demonstrate an encouraging trend to manufacturers of these products investing in research. Importantly, however, these studies have significant limitations that until now have not previously been addressed. For example, measures of bioavailability in horses have not acknowledged fundamental binding of glucosamine to serum proteins and as such likely provide gross underestimates. Other more general limitations include underpowered studies, unbalanced research design, non-existent or inappropriate controls, unclear or non-representative experimental conditions and uncharacterized or complex, heterogeneous experimental materials. Shortcomings such as these have heavily influenced interpretation, as well as misinterpretation, of results. Because of these substantial limitations, the existing data on glucosamine-based nutraceuticals for horses cannot be considered conclusive evidence supporting the efficacy of glucosamine-based nutraceutical products. Recommendations are made as to minimum scientific requirements for future research into glucosamine-based nutraceuticals for horses.

Introduction
Lameness is among the most important causes of poor performance in racing horses (Verheyen and Wood 2004). While non-steroidal anti-inflammatory drugs (NSAIDs) and corticosteroids remain important therapeutic resources for treatment of overt clinical lameness, nutraceuticals are becoming widespread as therapeutic and prophylactic management strategies for horses with low-grade, sub-acute articular damage and for those at risk of developing articular problems (Trumble 2005; Neil et al., 2005). It was more than 25 years ago that two German authors quietly associated supplementation of glucosamine to horses with improvement in clinical signs of joint disease (Jaeschke and Steinbach 1982). In the 25 years since, glucosamine and its related chemical chondroitin have become the most extensively used non-allopathic treatment for articular inflammation and arthritis in horses (Trumble 2005). The contemporary scientific literature abounds with new papers almost daily on glucosamine sulphate (GS), glucosamine hydrochloride (GH) and chondroitin sulphate (CS) for treatment of cartilage inflammation using a wide variety of animals, including humans. With this expanding body of knowledge on glucosamine arises a new scientific curiosity about the general principle of, and cellular basis for, treating equine arthritis and inflammation with glucosamine-based nutraceuticals.

In an industry well-accustomed to extrapolating in vitro data and data generated from research in non-equine species, it is encouraging to see scientific research appearing that attempts to directly investigate anti-arthritic nutraceuticals in horses. Importantly, these publications illustrate an encouraging trend to equine supplement manufacturers investing in product research to demonstrate safety and/or efficacy. Often, however, there are methodological and/or analytical compromises made in these investigations which impact the interpretation of the data and limit the conclusions that can be drawn. The purposes of this paper are to provide a critical review of the in vivo equine literature published between 1994 and 2006.
relevant to the use of glucosamine-based nutraceuticals, and to make recommendations for minimal essential criteria that should be adopted in future equine research in this area.

**In vivo studies in horses**

It is important that the experimental model chosen to test nutraceutical products provides a reasonable representation of the pathophysiological condition for which it is (to be) used as a prophylaxis or a treatment. For this reason, an early report of glucosamine-based nutraceuticals in horses (White et al., 1994) was not particularly useful for furthering our understanding of the effect of dietary glucosamine-based nutraceuticals for horses. However, White et al. (1994) made an important point with respect to the type of study designs that are not well suited to the assessment of nutraceutical products. The authors evaluated the effect of a dietary nutraceutical “Cosequin” (Nutramax; 9g twice daily for 30 days) on inflammation induced by intra-articular injection of Freunds Complete Adjuvant (FCA). Cosequin is a dietary product formulated for performance horses, and is composed of glucosamine hydrochloride (GH; 60%), chondroitin sulphate (CS; 20%), manganese (0.5%), ascorbate (3.5%) and undisclosed filler (16%). The authors concluded that Cosequin had no inflammatory effect in an equine model of inflammation induced by intra-articular FCA. FCA is a concentrated formulation of mycobacteria (usually Mycobacterium tuberculosis) in mineral oil. Injection of FCA results in a large increase in tumour necrosis factor-alpha (TNF-α) (Geboes et al., 2007), pronounced effusion and neutrophilia (Levy et al., 2000) and marked and sustained lameness (grade 4, AAEP scale; Toutain and Cester 2004; White et al., 1996). It is highly likely that this very rapid onset and severe model of inflammation overwhelmed any inflammatory pathways that had the potential to be inhibited by dietary Cosequin. This model of inflammation did not emulate the condition for which the product was intended; powerful drugs are typically used to treat acute, severe inflammation. In contrast, dietary nutraceuticals are generally applied as a preventative and/or to treat low-grade, chronic lameness (Trumble 2005). If a horse turned up lame in a stable to a similar magnitude as that induced by intra-articular FCA, it is extremely unlikely that horse would be treated with a dietary nutraceutical. Thus a negative result in this model does not further our understanding of the effectiveness of the product within a context of intended use. A second important limitation of this study is that, while the composition of the experimental product was provided, there was no confirmatory analysis of product label composition conducted by the investigators. This is not to suggest that the label information for the product was inaccurate; rather it is to demonstrate independently that the information is not inaccurate. A well-known characteristic of the nutraceuticals industry is one of inconsistent quality control (Oke et al., 2006), and confirmatory analysis of experimental products should become standard due diligence on the part of investigators.

In contrast to the White study, authors of a subsequent *in vivo* study of Cosequin concluded that the product was beneficial in arthritic horses (Hanson et al. 1997). Twenty five horses with degenerative joint disease received 9 (for horses < 500 kg) or 12g (for horses > 500kg) Cosequin twice daily for 6 weeks, and the authors reported improvements in lameness grade and stride length. The most important limitation to this study is that there was no control group maintained under similar conditions in the absence of supplementation with Cosequin. Thus it is not possible to determine whether the improved outcomes were due to normal healing as a function of time, reduced activity, supplementation with Cosequin, or to other confounding factors. Indeed, many cases of lameness in performance horses improve over time without any treatment at all (Ross et al., 1999), which suggests that the null hypothesis tested in this study (i.e. “baseline measurement and the following repeat examinations are the same”) had a good chance of being rejected even in the absence of any treatment. Some important discussion points missing from this study include the duration and aetiology of lameness of the experimental horses, records of exercise and/or rest after inclusion of horses in the study, and potential influences of differing diets or management strategies for the horses over the course of the study. Without at least this information the experimental data provide little useful information on the efficacy of the supplement. Unilateral study designs (without appropriate control groups) such as this can provide some useful information. But importantly, balanced interpretation is critical in that researchers need to acknowledge potential confounding factors to the reader in order to support the interpretations and conclusions made. So, like the White study, the experimental design of this study prohibits a conclusion addressing whether Cosequin actually does work in horses or not.

Caron et al. (2002) reported the *in vivo* effect of GH on serum markers of bone [osteocalcin (OC) and pyridinoline crosslinks of type-I collagen (PYD)] and cartilage [keratan sulphate (KS)] metabolism. Sixteen juvenile standardbreds in early race training completed the 48-week study. Nine treatment horses received 4g GH twice per day and 7 control horses received 4g glucose twice per day. GH had no effect on serum concentrations of OC, PYD or KS and, as such, the authors concluded that they were not able to obtain evidence that GH influences metabolism of bone or cartilage in growing and exercising horses. A number of factors influence the interpretation of these data. The choice of glucose as a placebo may be questioned because glucose can influence type I collagen expression *in vitro* (Zhang et al., 2007). Although the small amount of glucose fed in this study probably did not have a marked effect in the Caron study, there
are no data in the literature to confirm this. The control group in this study should have demonstrated a significant
decline in PYD over the time course of the protocol, an effect previously demonstrated in young exercising horses
(Brama et al., 2000) and growing chickens (Pedrini-Mille et al., 1988). The fact that this decline was not observed in
either the control or treatment group suggests that either the study was underpowered or that both the treatment
(glucosamine) and the control (glucose) influenced this particular dependent variable. This raises a major concern
regarding the absence of control groups for stage of growth or activity level of the experimental animals. The authors
acknowledge that they did not use a sedentary and/or mature control group for this study, but they inappropriately
dismiss this as unimportant to interpreting outcomes of the study. In fact, having no such controls leaves the authors and
readers with no way in which to tease out effects of growth and/or exercise from effects of glucosamine (or placebo) on
the serum levels of these biomarkers. The authors chose a model (exercise training) expected to significantly elevate OC
(Smith et al. 2007) and keratan sulphate (Yoon and Halper 2005); such an elevation has the potential to mask any
stimulatory effects of glucosamine on these biomarkers. An experiment quantifying the effect of glucosamine on steady-
state PYD, KS and OC, even in vitro, would be a useful prefix or adjunct to this study, and would improve the
interpretations that can be made from it.

In an 8-year study of 10 show hunter-jumpers (2 years prior to treatment + 6 years of dietary treatment of 10g/day of an
undisclosed glucosamine-based nutraceutical product), Rodgers (2006) reported a significant reduction in the frequency
of intra-articular injection of hyaluronan and steroid from an average of 1.7 to 0.85 injections per year. Also, the mean
duration between injections increased from 6.8 to 10.0 months after 2 or more years of supplementation, after which
there was no additional improvement. Rodgers (2006) concludes that the dietary glucosamine-based nutraceutical
decreases the need for distal tarsal joint injections to maintain soundness. This study did very well in considering a
number of confounding factors, appeared to have good control over lameness evaluations, and was long term. But the
study included only a small number of horses, and lacked any parallel control group. As such, it cannot be considered
“proof” that the benefits noted over time accrued primarily as a result of supplementation with the glucosamine–based
nutraceutical.

Forsyth et al. (2006) presents the most recent efficacy report of a glucosamine-based nutraceutical “Synoquin” for
improving articular function in horses. In this study, 20 mixed breed, mixed age elderly geldings and mares were
randomly allocated to treatment (n=15) or control (n=5) diet for 12 weeks. Treatment and control diets contained
Synoquin (VetPlus) or an equal amount of ‘filler’ – the composition of which is not disclosed in the paper. Synoquin is
composed of chondroitin sulphate (CS - 19% w/w), GH (50%), N-acetyl-D-glucosamine (5%) and filler (25%). The label
composition was not confirmed by the investigators. Given the heterogeneous profile of the horses and the unbalanced
allocation of horses to treatment and control groups, use of random assignment of horses to the groups is a limitation of
this study. Allocation of horses to the control group should have been stratified to be representative of horses in the
treatment group; this is particularly important because the control group (n=5) was substantially smaller than the
treatment group (n=15). Each horse in the control group should have represented characteristics of 3 horses in the
treatment group. Matching of control horses by sex, age, breed, and/or body mass with treatment horses would have
improved the validity of the of the data obtained. Furthermore, the baseline characteristics of horses allocated to each
group should have been provided, particularly as the data were only reported as mean change from baseline. Without any
information on what the baseline data were for each group it is not possible to determine whether the results indeed
reflect an improvement due to treatment, as concluded by the authors, or if the differences were simply artefacts of
differing baselines. The authors do report that the data were of equal variance, but presumably it was the transformed
data (i.e. ‘change from baseline’) that were of equal variance, and not the actual baseline means from each group. This is
a major limitation which substantially limits the conclusions that can be drawn from the data.

Bioavailability and pharmacokinetics
Bioavailability may be defined as the total amount of ingested substance that is absorbed across the gastro-intestinal tract
into the blood for distribution to tissues. Bioavailability of glucosamine is inherently difficult to measure accurately and,
in general, these difficulties often result in underestimates of bioavailability. Important considerations when evaluating
bioavailability of glucosamine in any species include: (1) there is substantial first pass removal of glucosamine by
intestinal epithelial cells and the liver in all mammals which has been quantified (humans, dogs and rats; reviewed by
Setnikar and Rovati 2001, Anderson et al. 2005); (2) the parent compound or its metabolites may be metabolized by cells
of the blood, gastrointestinal tract and/or the liver; (3) glucosamine is very rapidly bound to plasma globulins, such that
less than 1% of glucosamine remain free in plasma. Therefore when plasma proteins are precipitated prior to analysis of
the supernatant for glucosamine, the glucosamine may effectively be precipitated along with the protein resulting in net
analysis of only free glucosamine. Thus, it may be erroneously concluded that the bioavailability of glucosamine in
horses is very low (2.5 or 5.9%; Du et al 2004 and Laverty et al. 2005, respectively). In this regard it is important to note
that even though glucosamine is transported within the circulation bound to globulins, it does appear to remain in dynamic equilibrium with free plasma glucosamine and hence is capable of being rapidly extracted by virtually all cells receiving nutritive blood flow. In humans, dogs and rats the absolute oral bioavailability of glucosamine, based on the globulin-incorporated radioactivity of $^{14}$C-labelled glucosamine, is 40-45%, with g.i. absorption as high as 88% of the administered dose (Setnikar and Rovati 2001).

There are other inherent difficulties in studying the bioavailability and kinetics of glucosamine and glucosamine-based nutraceuticals. Glucosamine is an endogenous substance that can be formed within cells using glucose as a precursor. Due to its structural similarity to glucose, its is a competitor in glucose transport, probably via GLUT1 in hepatocytes (Uldry et al., 2002) or GLUT3 in chondrocytes (Windhaber et al., 2003). Glucosamine is incorporated into joint tissues other than cartilage. Indeed, in a review of their detailed pharmacokinetic studies in mammals, Setnikar and Rovati (2001) noted that 2 h after administration of $^{14}$C-labelled glucosamine, is 40-45%, with g.i. absorption as high as 88% of the administered dose (Setnikar and Rovati 2001).

The second equine glucosamine / chondroitin bioavailability and pharmacokinetics study (Laverty et al., 2005) addressed some of the limitations noted in the former study. In this study 8 horses received i.v. or oral doses of GH at 20mg/kg – a dose was determined by collecting jugular venous blood over a 12 hour period. Synovial fluid was also obtained from each horse at 0, 1 and 12 hours after dosing in order to quantify hypothesized increases in synovial fluid GH. As with Du et al. (2004) study is challenged by others, who report human synovial fluid concentrations of glucosamine only about 25% lower that of blood after dosing (Persiani et al., 2007). It is unlikely that this simply reflects a species difference. Perhaps most important is that synovial fluid glucosamine was determined after 2 weeks of oral dosing with GS (Persiani et al., 2007) whereas Laverty et al. (2006) described accumulation 12 hours after a single oral dose. While there was no attempt at time-course assessment of glucosamine in human synovial fluid, Persiani et al. (2007) were likely detecting an accumulation of glucosamine over time, consistent with the reported accumulation of chondroitin sulphate in canine synovial fluid a period of repeated dosing (Adebowale et al., 2002).

Another important consideration is that the increase in synovial fluid GH represents only the net effect of free GH transport into synovial fluid. This includes uptake of glucosamine by cells within the joint, binding to other molecules, and incorporation into joint structures. Indeed, in a review of their detailed pharmacokinetic studies in mammals, Setnikar and Rovati (2001) noted that 2 h after administration of $^{14}$C-labelled glucosamine to rats and dogs, the radioactivity accumulated in the knee cartilage of the treated animals to values 13-fold greater than in plasma. Therefore, it is unlikely that the discrepancy is just a species difference. It is not clear why the researchers performing the
glucosamine bioavailability studies in horses did not quantify the total plasma glucosamine concentrations. They were seemingly aware of this literature, yet neglected to even mention its importance in determining bioavailability and discuss the impact on tissue distribution.

While a definitive conclusion as to the bioavailability and fate of oral glucosamine in horses has not been provided by these two equine studies, they do support at least 2 important hypotheses:

1.) glucosamine and chondroitin are absorbed from the intestinal tract of horses

2.) glucosamine does appear in the synovial fluid of horses

**General recommendations for future research and Conclusions**

Further studies, accounting for total plasma glucosamine, and preferably using larger numbers of horses to account for the wide variability in individual horse responses to dietary glucosamine, are needed to more clearly define the differential bioavailability and post-absorptive behaviour of GH, GS, and CS in horses. It might also be interesting to look at the post-dosing intracellular glucosamine or glucosamine metabolite content of equine erythrocytes as this may be a significant sequestration compartment for this species. Glucosamine is often administered to performance horses in order to pre-empt or treat joint disease (Trumble 2005). It is possible that glucosamine is actively transported into erythrocytes and because equine hematocrit can increase to more than 60% of total blood volume during high intensity exercise (Catalani et al., 2007), erythrocyte distribution and fate may be an important consideration in this species. Furthermore, glucosamine-based nutraceuticals are administered to horses almost exclusively as part of the diet. Thus, bioavailability and pharmacokinetics of glucosamine in the presence of a normal meal would provide meaningful information on what can be expected of the supplement under normal conditions of use.

Species-specific research into glucosamine-based nutraceuticals for horses has, as yet, failed to produce substantial evidence for the functionality of these products in this species. Conclusions of both ‘effective’ and ‘not effective’ in the peer reviewed equine literature have been compromised to varying degrees by numerous experimental factors including underpowered studies, unbalanced research design, non-existent or inappropriate controls, unclear or non-representative experimental conditions (i.e. models) and uncharacterized or complex, heterogeneous experimental materials. Future studies on glucosamine-based nutraceuticals in horses need to embrace fundamental experimental paradigms in design and interpretation of data. Use of appropriate statistical methods for determining sample size will reduce the problem of underpowered studies. Studies should have balanced treatment and control groups, and the experimental material should be independently characterized by the investigators – i.e. investigators should perform confirmatory analysis on label composition and purity. Experimental research designs should reflect the expected conditions of use, and placebos should be chosen such that they have confirmed inactivity in the experimental model or condition. The improved application of sound scientific principles to the assessment of glucosamine and its related nutraceutical products will lead to a better understanding of the role that this class of products can play in supporting joint health in horses.
